Field of the Invention

30 This invention relates to the field of stored program controlled systems,
including, but not limited to, telephone switching offices, data routers, and robotic
machine tools; and, more specifically, this invention describes an optical

communication path providing communication among processing units in a stored program controlled system.

Background of the Invention

The background of the present invention may be summarized in one word: "wires". Most stored program controlled systems of even minor complexity consist of a plurality of single or limited functionality processing units, each of which is connected to one or more of the other processing units by wires. There are literally millions of miles of interconnecting wires in current use in systems as diverse as stored program controlled telephone and data switching systems, robotic assembly lines, high speed mainframe computers, modern aircraft, local area networks, etc.

These wires provide the medium for communication signals among processing units to facilitate functionality of the whole. For example, a signal generated by a processing unit in the cockpit of an airplane is transmitted over a wire to a processing unit in the tail section to manipulate the tail control surfaces. Likewise, in a stored program controlled telephone switching office, a signal to connect a telephone call from one line to another is carried by wires interconnecting the processing units to which the telephone lines are connected.

In most stored program control systems, the "interconnecting wires" is a complex array of backplane wiring interconnecting processing units on cards, shelves of cards and cabinets of shelves. Each of these (card, shelf of cards, cabinet of shelves) may be considered a "processing unit", because cards and shelves of related tasks are usually wired together in functional units, and then generally wired together in a cabinet. Cabinets of large stored program controlled systems are interconnected by bundles of wires (cables). Thus, the interconnecting wires provide communications paths that enable the individual processing units of the stored program controlled system to interact, thus providing the functioning of the whole.

A single change in an individual processing unit of a stored program controlled system may cause literally thousands of interconnecting wires to be moved from one processing unit to another, or connected or reconnected in some fashion. These new connections must be carefully planned and executed by skilled craftspeople

C. C. Byers 39-1

who make each connection and then test it. One minor error may cause a major malfunction.

Further, these wires are bulky and are frequently grouped together into a cable bundle. Such bundling is problematic in and of itself; in that, if one or more wires in the bundle is cut, then some or all of the functionality of the stored program controlled system is lost, and it is difficult to find one damaged wire in a bundle of wires. In a worst case scenario, a single short in a bundle of wires can cause devastating fires, such as the fire in the telephone switching office in Hinsdale, Illinois in May of 1988. This fire caused a nationwide disruption of telephone service that lasted for a few days and interruption of local telephone service that lasted for several months.

Over the past decade, some interconnecting wire has been replaced by fiber optical cable. This was an advance in the art, because more signals (higher bandwidth) are carried over a smaller physical cross-section. However, fiber optics has been treated for the most part like another wire: each fiber connects one processing unit to another, the optical signal is converted between optical and electrical signals at each terminus, and the electrical signals are processed in the usual fashion.

Therefore, a problem in the art is that processing units in a stored program controlled processing system are interconnected by extensive wiring which is difficult to install, maintain and modify.

Summary of the Invention

This problem is solved and a technical advance is achieved in the art by a system and method that uses free space optics to interconnect processing units of a stored program controlled system. Communication signal paths are provided in a stored program controlled system comprising a plurality of units configured to process signals ("processing units") by a beam line in free space, proximal to each of the plurality of units. The beam line is configured to contain optically encoded communications signals that are transmitted between and among the processing units. Each processing unit includes a probe for receiving optically encoded signals from the beam line, and, advantageously, a probe for injecting optically encoded signals into the beam line. There may be a first terminal unit at a first end of the beam line

configured to originate and/or terminate the optically encoded signals and a second terminal unit at the second end of the beam line also configured to originate and/or terminate the optically encoded signals.

Each processing unit may comprise a frame, a shelf, or an individual card on a shelf of the stored program controlled system, and each processing unit performs functions related to the stored program controlled system's intended functionality. Probes are configured to receive or send optically encoded signals in the free space beam line. The probe further comprises supporting circuitry to translate optically encoded signals into and out of electrically encoded signals, and route such signals.

The beam line may run above, below, through or adjacent to the processing units and the beam may be encoded in time division multiplexing, spatial division multiplexing or wavelength division multiplexing. The beam line may be formed and directed using routing mirrors, prisms, lenses, gratings and holograms.

Brief Description of the Drawings

A more complete understanding of this invention may be obtained from a consideration of the specification taken in conjunction with the drawings, in which:

FIG. 1 is a perspective view of a free space beam line illustrating the relationship of the beam line and probes according to a general overview of an exemplary embodiment of this invention;

FIG. 2 is a cross-sectional view of the free space beam line taken along line 2-Z of FIG. 1;

FIG. 3 is an exemplary embodiment of transmitting and receiving probes of FIG's. 1 and 2;

FIG. 4 is another exemplary embodiment of transmitting and receiving probes of FIGs. 1 and 2;

FIG. 5 is a block diagram of uni-directional communication along a free space beam line according to one exemplary embodiment of this invention;

FIG. 6 is a block diagram of a further exemplary embodiment of this invention having bi-directional probes;

FIG. 7 is a block diagram of another exemplary embodiment of this invention wherein each of the processing units may communicate with each other;

C. C. Byers 39-1

FIG. 8 is a physical layout of a stored program controlled switching office according to an exemplary embodiment of this invention;

FIG. 9 is a block diagram of the exemplary embodiment of FIG. 8 in which the free space beam line is distributed to each shelf; and

5 FIG. 10 is a block diagram of the exemplary embodiment of FIG. 8 in which the free space beam line is distributed to each card on each shelf.

Detailed Description

Turning to FIG. 1, a perspective view of a free space beam line 10 according to one exemplary embodiment of this invention is shown. According to this exemplary
10 embodiment, a free space beam line 10 is generated by a transmitter 12 within a transmitting probe 14 which projects optically encoded signals, as will be described below in connection with FIGs. 3 and 4. Transmitting probe 14 produces a beam line 10 of desired diameter along the length of its path.

A plurality of receivers 16 within receiving probes 18 are distributed
15 throughout beam line 10 along the outer periphery in the form of a spiral or helix, in this exemplary embodiment. Other possible configurations of probes along the beam line will be apparent to one skilled in the art after studying this disclosure. Receiving probes 18 are distributed in a helix in this exemplary embodiment so that there is a minimal amount of shadowing; that is, one receiving probe 18 being in the shadow of
20 a previous receiving probe 18 in beam line 10 causing the probe in the shadow to receive little or none of the optically encoded signals in beam line 10.

Free space beam line 10 may be contained within a reserved volume or conduit 22, in an enclosure, such as a cylinder or pipe or, alternatively, may be in the open. If the beam line 10 is contained in a conduit, then the interior surface may be coated at
25 the time of manufacture to be optically absorptive or optically reflective depending upon the length of the pipe, the wavelength of the signal generated by the laser within transmitter 12 and loss budget to provide optimal reception of optically encoded signal by the plurality of receiving probes 18 throughout the length of beam line 10.

Conduit 22 includes, in this exemplary embodiment, a first terminal unit 24
30 and a second terminal unit 26. First terminal unit 24 includes a transmitting probe 14 and second terminal unit 26 includes a receiving probe 18, in this exemplary

embodiment. First terminal unit 24 originates optical beam line 12 and second terminal unit 26 terminates the portion of optical beam line 12 passing beyond the other probes 18. As will be discussed further, below, first terminal unit 24 and/or second terminal unit 26 may include both transmitters and receivers, and may be interconnected to recycle the encoded signal.

FIG. 2 illustrates a view looking down a cross-section of free space beam line 10 taken along line 2-2 of FIG. 1. Conduit 22 includes a plurality of receiving probes 18 around its inner edge. In the illustration of FIG. 2, the laser of transmitter 12 (Fig. 1) focuses beam line 10 to encompass the interior circumference of conduit 22 whereby each probe 18 receives the encoded optical signal. Second terminal unit 26 is illustrated herein as comprising a receiving probe 18. (Second terminal unit may also include a transmitter 12, not shown.) Alternatively, second terminal unit 26 may comprise an end cap. An end cap may be absorptive in order to stop the beam line 10 or may be reflective (i.e., a mirror or retroreflector) to recycle beam line 10 in the opposite direction.

Turning now to FIG. 3, exemplary embodiments of a transmitting probe 14 and a receiving probe 18 are shown. In this exemplary embodiment, transmitting probe 14 includes a transmitter 12 comprising a laser 30 (i.e., a laser diode 32 and a feedback photodetector 34, as known in the art), which converts electronically encoded signals into free space optical beam line 10. Free space optical beam line 10 is projected through a concave lense 36 and a convex lense 38 (which form a reverse Galilean telescope, as is known in the art). A laser driver 40 feeds electrically encoded signals to, and receives feedback from, laser 30, as known in the art. Feedback amplifier 42 regulates the input to laser 30. Laser 30 and laser driver 40 are both known to those skilled in the art. Laser 30 and laser driver 40 are illustrated herein as two separate units, but may be one unit.

Free space beam line 10 is received at a receiving probe 18 at a receiver 16, which includes a convex lense 44 that focuses beam line 10 on a photodetector 46. Photodetector 46 receives a portion of beam line 10 and generates an electrical signal in response thereto. The electrical signal is fed into a receiver circuit 48 comprising a trans-impedance amplifier (TIA) 50, clock recovery circuit 52 and decision circuit 54.

C. C. Byers 39-1

Receiver 16 and receiver circuit 48 are well known in the art. Receiver 16 and receiver circuit 48 are illustrated herein as two separate units, with receiver circuit 48 contained within a signal receiver 55. However, these two units may be one unit, as is known in the art.

5 Laser 30 is driven by an electrical signal from signal generator 56. Signal generator 56 comprises laser driver 40, protocol handler 58 and multiplexer 60. Multiplexer receives multiple inputs 62 from one or more processing units, which are multiplexed according to a predetermined algorithm (many algorithms for multiplexing are known in the art and are thus not discussed here). Signals are then
10 passed to protocol handler 58. Protocol handler 58 encapsulates the signals with the protocol used by the beam line 10. Such protocols are described in U.S. Patent Applications Attorney Docket Nos. Byers 41-3, Byers 42-4 and Byers 43-5 which are incorporated by reference, above. The signal generated by protocol handler 58 is fed into laser driver 40, which controls laser 30.

15 When a signal is received by photodetector 46, it is delivered to signal receiver 55, which comprises receiver circuit 48, protocol handler 64 and demultiplexer/router 66. The received signal is decoded in receiver circuit 48, as known in the art. The receiver circuit 48 is connected to a protocol handler 64 which de-encapsulates the signal received according to the protocol used by protocol handler 58. Protocol
20 handler 64 passes the signal to a demultiplexer and router 66 which demultiplexes the signal and then sends signals 68 to the receiving processing unit or units. Demultiplexing and routing algorithms are well known in the art, and are thus not further described.

FIG. 4 illustrates an exemplary embodiment of a transmitting probe 14 and a
25 receiving probe 18 according to another aspect of this invention. In this exemplary embodiment, the electronics are remote from the optical beam line. Transmitting probe 14 in this exemplary embodiment includes a transmitter 12 comprising a laser element 30, as described above in connection with FIG. 3, which changes electrical signals delivered from laser driver 40 into an optically encoded signal. Optionally,
30 this optically encoded signal is fed into lense 80, which projects the signal through light guide 82 (i.e., optical fiber) in this exemplary embodiment. One skilled in the art

C. C. Byers 39-1

will appreciate that some applications will not require lense 80. Fiber optic conduit 82 projects the optically encoded signal through lenses 36 and 38 (the reverse Galilean telescope as described above) which forms free space beam line 10.

Receiving probe 18 includes a receiver 16, a lense 306 that focuses light from beam line 10 onto fiber optic conduit 86. Fiber optic conduit 86 transmits the optical signal through lense 88 onto photodetector 46. Photodetector 46 sends an electrical signal through receiver circuit 48, protocol handler 64 and demultiplexer/router 66, as described above. The signals are delivered to their respective processing unit or units via lines 68.

FIG. 5 is a block diagram of a stored program controlled system 100 in a basic implementation of an exemplary embodiment of this invention. Stored program controlled system 100 may comprise, in this exemplary embodiment, a uni-directional local area network. In the stored program controlled system 100, a first processing unit 102 comprises a controller which distributes signals to a plurality of processing units 104, 106, 108 and 110. Processing units 104, 106, 108 and 110 receive signals from controller 102 via receiving probes 18 (as described above) and perform their respective functions on received signals.

In this one-way communication system, processing unit (controller) 102 passes commands to processing units 104, 106, 108 and 110 without expecting responses from any of the processing units. Controller 102 generates signals to control processing units 104, 106, 108 and 110 and encodes the signals into a form that can be translated into optical signals (as discussed above in connection with FIG's. 3 and 4). Controller 102 is connected to a transmitting probe 14 in a first terminal unit 24 in this exemplary embodiment.

A free space beam line 10 is thus formed containing the optically encoded signals for processing units 104, 106, 108 and 110. The exemplary embodiment of FIG. 5 includes a conduit 22. Conduit 22 includes an end cap 112 (instead of a second terminal unit) which may be coated with light absorptive or alternatively reflective material, depending upon which direction the receiving probes 18 are facing.

According to this invention, the entirety of free space beam line 10 is filled with optically encoded signals as it exits terminal unit 24. In this embodiment, each

probe receives the optically encoded signal directly. Alternatively, lenses 36 and 38 in transmitter 12 (FIG. 3) of transmitting probe 14 may focus the beam line 10 so that it does not completely fill conduit 22 until it hits end cap 112. End cap 112 comprises reflective surface in this exemplary embodiment, which provides a full beam line 10 throughout conduit 22. Considerations of signal strength, beam divergence, bit rate, distance between processing units 104, 106, 108 and 110, signal to noise ratio, etc. must be taken into account to determine which method (direct or reflective) of transmission is preferable in a given application.

Turning now to FIG. 6, an exemplary embodiment of this invention using bi-directional probes is shown generally at 120. In this exemplary embodiment, processing unit (controller) 122 communicates with a plurality of processing units 124, 126, 128, and 130. As in the previous exemplary embodiments, controller 122 communicates with a first terminal unit 24, which includes a transmitting probe 14 that produces free space beam line 10. Beam line 10 is, in this exemplary embodiment, unenclosed.

Each processing unit 124, 126, 128 and 130 has an associated receiving probe 18 for receiving signals from controller 122. Additionally, each processing unit 124, 126, 128 and 130 includes a transmitting probe 14 to transmit return signals to receiving probe 16 in terminal unit 24. The received signals are delivered to controller 122, which then processes these signals for further control of the stored program controlled unit, creating a full-duplex channel.

Turning now to FIG. 7, a further exemplary embodiment of this invention is shown. In this exemplary embodiment, free space beam line 10 is uni-directional, i.e., signals flow in the direction from uni-directional first terminal unit 132 to second uni-directional terminal unit 134 and are then recirculated, as will be described further below. Free space beam line 10 is enclosed in conduit 22. In this exemplary embodiment, a processing unit controller 136 and processing unit 138, 140, 142 and 144 are each connected to a respective transmitting probe 14. Processing units 138, 140, 142 and 144 are connected to respective receiving probes 18. Terminal 134 uses terminal receiving probe 135.

In the exemplary embodiment of FIG. 7, processing unit or controller 136 originates electrical control signals for processing units 138, 140, 142 and 144 and communicates such signals to router 146. Router 146 comprises a conventional router as is known in the art. Router 146 communicates signals for processing units 138, 140, 142 and 144 to a signal generator 56 (as described above in connection with FIG. 3). Transmitter 14 in uni-directional first terminal unit 132 optically encodes the signals, and transmits optical beam line 10. Receiving probes 18 receive the optically encoded signals and convey them to their respective processing unit 138, 140, 142 and 144. Each processing unit 138, 140, 142 and 144 may send feedback or other information to controller 136 by injecting signals into free space beam line 10, which are all received at terminal receiving probe 135 in uni-directional second terminal unit 134. The signals are then fed back to router 146 where they may be further circulated in beam line 10 or delivered to controller 136.

Systems using many of the embodiments of this invention (*i.e.*, FIG. 7) must include features to prevent messages from recirculating in free space beam line 10. If these features are not included, infinite feedback loops are possible, where a single message is continuously relayed between two endpoints and/or probes, quickly absorbing all available bandwidth. To prevent this, a means to break these loops is provided. Router 146 is programmed (or programmed in conjunction with the probes or endpoints) to detect addresses that lead to looping and not forward those messages back into the beam line. Alternately, the optical characteristics of the beam line, transmitters and receivers are controlled to prevent messages from a given source from circulating indefinitely.

FIG. 8 presents a block diagram of one exemplary embodiment of a stored program controlled system which uses a free space optical beam line 10 to interconnect its processing units. In this exemplary embodiment, the stored program controlled system comprises a telephone switching system 200, such as a 5ESS[®] Switch or 7R/E Switch manufactured by Lucent Technologies. There are a plurality of processing units 202, 204, 206, 208, 210 and 212. Processing units 202, 204, 206, 208, 210 and 212 comprise "frames" as are known in the art. Each frame comprises a plurality of shelves 214 and on each shelf is one or more cards 216 (also called

C. C. Byers 39-1

"boards" in the art). Each card 216 performs one or more predefined functions, as is known in the art.

In the exemplary embodiment of a SESS[®] Switch, frame 202 comprises a communications module (CM) which effects communication among the other frames
5 in the system. Frame 204 comprises an administration module (AM) which provides overall control of the system and human-machine interface. Frames 206, 208, 210 and 212 comprise switch modules (SMs), which support a plurality of line and/or trunk units (or some combination thereof) and effect connections of telephone or data calls. All of the processing units (frames 202, 204, 206, 208, 210 and 212) communicate
10 with each other (generally through CM 202) in order to switch telephone calls.

Currently, frames such as 202, 204, 206, 208, 210 and 212 are interconnected by a plurality of wire buses and/or optical fiber carried in overhead trays or under raised floors. Wiring a new office or even adding a new frame may cause the installation team to revisit the entire wiring of the system in order to ensure proper
15 functionality of the whole stored program controlled system 200 when connected. This invention is intended to replace the current industry standard of wiring between and among frames in central switching offices. This invention eliminates the probability of accidental damage to cabling, decreases new installation and upgrade time. The following exemplary embodiment of this invention is described in the
20 context of such a central switching office. It is, however, clear to one skilled in the art how to implement and use this invention in other applications after a review of this patent application.

According to one exemplary embodiment of this invention, a free space optical beam line 10 provides interconnection of the frames 202, 204, 206, 208, 210 and 212.
25 Signals are carried on one or more optical wavelengths as is known in the art. There may also be a pilot beam 218 in the visible light wavelengths in order to aid craft personnel to align probes 14 & 18 of the processing units and other optical components.

In this exemplary embodiment, each processing unit 202, 204, 206, 208, 210
30 and 212 includes a transmitting probe 14 and a receiving probe 18 positioned in beam line 10 in order to send and receive, respectively, signals in system 200. Each

C. C. Byers 39-1

transmitting probe 14 and each receiving probe 18 may, advantageously, be bi-directional. It is within the scope of one skilled in the art to make the transmitting and receiving probes of FIG's. 3 and 4 transmit/receive in both directions after reading this specification. Transmitting probe 14 and receiving probe 18 on frame 202 comprise a
5 first terminal unit 24 and transmitting probe 14 and receiving probe 18 on frame 208 comprise a second terminal unit 26. The probes 14 and 18 in first terminal unit 24 and second terminal unit 26 may be uni-directional.

Each transmitting probe 14 is connected to a signal generator 56 and each receiving probe 18 is connected to a signal receiver 55. Signal generator 56 and signal
10 receiver 55 may be separate cards 216 as illustrated, may be one integrated card, or may both be integrated with other functionality of its respective shelf 214 and/or frame 202, 204, 206, 208, 210 or 212.

Additionally, first terminal unit 24 may be connected to second terminal unit 26 by way of a connector 220. Routers 222 and 224 are illustrated herein as
15 connecting connector 220 to first terminal unit 24 and second terminal unit 26, respectively. Ordinary routers 222 and 224 may route selected messages between terminal units 24 and 26, and to prevent endless looping of messages. Connector 220 may comprise another free space optical conduit like beam line 10, or may comprise a fiber optic or electrical link as is known in the art.

Free space beam line 10 may be manipulated by turning mirrors 226, prisms or the like (not shown but well known in the art) to provide, for example, a continuous
20 beam line 10 through multiple rows of processing units (or floor levels, etc.). Beam line 10 is illustrated as running above the processing units in FIG. 1. Beam line 10 may also run under a raised floor, or in a space or conduit otherwise adjacent to or
25 through the processing units.

Turning now to FIG. 9, another exemplary embodiment of this invention is shown, wherein "processing units" are defined at one level below a frame. In this exemplary embodiment, free space beam line 10 is shown, as described above. Each frame, for example, frame 204, comprises a plurality of shelves 214, here shown as
30 214A - D. In this exemplary embodiment, a turning mirror 226 is set in main beam line 10 to turn main free space beam line 10 into frame-level free space beam lines

C. C. Byers 39-1

228. In this exemplary embodiment, transmitting probes 14 and receiving probes 18 send and receive optical signals for each shelf 214A - D. End cards 230 on each shelf 214A - D comprise signal generators 56 and signal receivers 55 (not shown) as described above in connection with FIG. 3. Mirrors 226 may be partially reflective so as to turn a portion of the signal beams and allow another portion to pass through, as is known in the art.

Turning now to FIG. 10, another exemplary embodiment is shown, wherein a "processing unit" is now defined as a card 215. Turning mirrors 226 are again used to turn main free space beam line 10 into frame free space beam lines 228. Each shelf 214A - 214D includes a pair of additional card level turning mirrors 240 in beam lines 228, respectively. Card level turning mirrors 240 provide card free space beam lines 242. There may be one or more card level beam lines 242 per shelf 214. In this exemplary embodiment, there are two free space beam lines 242 per shelf. Each shelf 214 then includes at least one card 216 equipped with a transmitting and/or receiving probes 14 and 18 (as illustrated in FIG. 3) and the supporting signal generator and signal receiver.

Frame probe 249 is used for frame-level communication and control functions. For example, power control, temperature sensing and alarm enunciation may be communicated to a central control by frame probe 249.

It is to be understood that the above-described embodiments are merely illustrative principles of the invention and that many variations may be devised by those skilled in the art without departing from the scope of this invention. It is, therefore, intended that such variations be included within the scope of the following claims.
